ABSTRACT
Group signatures have recently become important for enabling privacy-preserving attestation in projects such as Microsoft’s NGSCB effort (formerly Palladium). Revocation is critical to the security of such systems. We construct a short group signature scheme that supports Verifier-Local Revocation (VLR). In this model, revocation messages are only sent to signature verifiers (as opposed to both signers and verifiers). Consequently there is no need to contact individual signers when some user is revoked. This model is appealing for systems providing attestation capabilities. Our signatures are as short as standard RSA signatures with comparable security. Security of our group signature (in the random oracle model) is based on the Strong Diffie-Hellman assumption and the Decision Linear assumption in bilinear groups. We give a precise model for VLR group signatures and discuss its implications.

1. INTRODUCTION
Group signatures, introduced by Chaum and van Heyst [11], provide anonymity for signers. Each group member has a private key that enables him to sign messages. However, the resulting signature keeps the identity of the signer secret. Often there is a third party that can undo the signature anonymity (trace) using a special trapdoor [11, 1]. Some systems support revocation [10, 2, 21, 12], where group membership can be disabled without affecting the signing ability of unrevoked members. Currently, the most efficient constructions are based on the Strong-RSA assumption introduced by Baric and Pfitzman [3]. These signatures are usually much longer than RSA signatures of comparable security.

A number of recent projects require properties provided by group signatures. One such project is the Trusted Computing effort (TCG) [20] that, among other things, enables a desktop PC to prove to a remote party what software it is running via a process called attestation. Group signatures are needed for privacy-preserving attestation [9]. To enable attestation, each computer ships with an embedded TCG tamper-resistant chip that signs certain system components using a secret key embedded in the chip. During attestation to a remote party (e.g., a bank) these signatures are sent to the remote party. To maintain user privacy it is desirable that the signatures not reveal the identity of the chip that issued them. To do so, each tamper resistant chip issues a group signature (rather than a standard signature) on system components that it signs. Here the group is the set of all TCG-enabled machines. The group signature proves that the attestation was issued by a valid tamper-resistant chip, but hides which machine it comes from. We refer to this as privacy-preserving attestation. Revocation is critical in such systems—if the private key in a TCG chip is exposed, all signatures from that chip must be invalidated since otherwise attestation becomes meaningless.

In this paper we focus on a revocation model that is motivated by privacy-preserving attestation. At a high level, one can consider three natural communication models for revoking a user’s signing capabilities, without affecting other group members:

1. The simplest method revokes user i by issuing a new signature verification key and giving each signer, except user i, a new signing key. This requires an individual secret message to each signer (e.g., TCG chip) and a public broadcast message to all verifiers.

2. A better revocation mechanism sends a single short public broadcast message to all signers and verifiers. A recent system by Camenisch and Lysyanskaya [10] provides such a mechanism.

3. Brickell [9] proposes a simpler mechanism where revocation messages are only sent to signature verifiers, so that there is no need ever to communicate with an end-user machine. A similar mechanism was considered by Ateniese et al. [2] and Kiayias et al. [14].

In this paper we formalize the concept of VLR group signatures. In Section 2 we give a precise definition of security using the framework of Bellare et al. [4]. We discuss the mechanics of working with VLR group signatures and the features they provide. In Section 4 we present our short VLR group signature scheme. Signatures in our system are about the same length as standard RSA signatures of comparable security. Security is based on the Strong Diffie-Hellman (SDH) assumption [6] in groups with a bilinear map. We also need the Decision Linear assumption, an assumption that has proven useful for constructing short group signatures [7].

VLR group signatures are implemented by giving the signature verification algorithm an additional argument called the Revocation List (RL). The RL contains a token for each revoked user. The verification algorithm accepts all signatures issued by unrevoked users and reveals no information about which unrevoked user issued the signature. However, if a user is ever revoked (by having his revocation token added to the RL), signatures from that user are no longer accepted. It follows that signatures from a revoked user become linkable: to test that two signatures were issued by the same revoked user, verify the signatures once using the RL before the user is revoked and once using the RL after. As a result, users who break the tamper resistance of their TCG chip and are revoked deliberately lose their privacy. Our specific VLR group signatures have an additional useful property: given a user’s private key it is easy to derive that user’s revocation token—the revocation token is the left half of the private key. Hence, any private key that is published on the web can be trivially added to the RL and revoked. This potentially eliminates the need for a trusted revocation authority. Instead, revocation could be done by just scanning the web and newsgroups for exposed private keys and telling all signature verifiers to add these keys to their RL. We discuss this in more detail in the next section.

**Notation.** Throughout the paper we use boldface to denote a vector of elements such as $gsk$. We use $gsk[i]$ to denote the $i$th element of the vector $gsk$.

## 2. Verifier-Local Revocation

A verifier-local group signature scheme comprises three algorithms, KeyGen, Sign, and Verify, which behave as follows:

* **KeyGen**($n$). This randomized algorithm takes as input a parameter $n$, the number of members of the group. It outputs a group public key $gpk$, an $n$-element vector of user keys $gsk = [gsk[1], gsk[2], \ldots, gsk[n]]$, and an $n$-element vector of user revocation tokens $grt$, similarly indexed.

* **Sign**($gpk$, $gsk[i]$, $M$). This randomized algorithm takes as input the group public key $gpk$, a private key $gsk[i]$, and a message $M \in \{0,1\}^*$, and returns a signature $\sigma$.

* **Verify**($gpk$, $RL$, $\sigma$, $M$). The verification algorithm takes as input the group public key $gpk$, a set of revocation tokens $RL$ (whose elements form a subset of the elements of $grt$), and a purported signature $\sigma$ on a message $M$. It returns either valid or invalid. The latter response can mean either that $\sigma$ is not a valid signature, or that the user who generated it has been revoked.

### Implicit Tracing Algorithm

Any VLR group signature scheme has an associated implicit tracing algorithm that, using a secret tracing key, can trace a signature to at least one group member who generated it. The vector of revocation tokens, $grt$, functions as this secret tracing key. Given a valid message-signature pair $(M, \sigma)$, a party possessing all the revocation tokens $grt$ can determine which user issued the signature using the following algorithm:

1. For each $i = 1, \ldots, n$ run the verification algorithm on $M, \sigma$ with revocation list $RL = \{grt[i]\}$.
2. Output the index of the first user for which the verification algorithm says invalid. Output fail if the signature verifies properly for all $n$ users.

Our security definitions below explain why this is a correct tracing algorithm. The algorithm above demonstrates that the $grt$ vector can function as a secret tracing key, if so desired. Note that $grt$ in our system can be derived from just one value so that there is no need to store a large vector as a tracing key.

In the constructions we have in mind, a user can derive her revocation token from her private key, and can therefore determine whether her key was used to generate a particular signature. We refer to this as **selfless-anonymity**: a group member can tell whether she generated a particular signature $\sigma$, but if she didn’t she learns nothing else about the origin of $\sigma$. We describe a new security model that captures this notion. We use the framework of Bellare et al. [4].

A secure VLR group signature scheme must satisfy three requirements: correctness, traceability, and selfless-anonymity. We describe each in turn.

### Correctness

This requires that, for all $(gpk, gsk, grt)$ generated by the generation algorithm, every signature generated by a user verify as valid, except when the user is revoked; or, formally, that

$$\text{Verify}(gpk, RL, \text{Sign}(gpk, gsk[i], M), M) = \text{valid} \iff grt[i] \notin RL.$$ (1)

### Traceability

We say that a VLR group signature scheme is traceable if no adversary can win the traceability game. In the traceability game, the adversary’s goal is to forge a signature that cannot be traced to one of the users in his coalition using the implicit tracing algorithm above. Let $n$ be a given group size. The traceability game, between a challenger and an adversary $A$, is defined as follows.

**Setup.** The challenger runs algorithm KeyGen($n$), obtaining group parameters $gpk$, $gsk$, and $grt$. He provides the adversary $A$ with $gpk$ and $grt$, and sets $U = 0$.

**Queries** Algorithm $A$ can make queries of the challenger, as follows.

**Signing.** Algorithm $A$ requests a signature on an arbitrary message $M$ for the user at index $i$,
In the selfless-anonymity game, the least adversary's goal is to determine which of two keys generates traceability in an coalition, and responds with \( gsk[i] \).

**Response.** Finally, forger \( A \) outputs a message \( M^{*} \), a set \( RL^{*} \) of revocation tokens, and a signature \( \sigma^{*} \).

The forger wins if: (1) \( \sigma^{*} \) is accepted by the verification algorithm as a valid signature on \( M^{*} \) with revocation-token set \( RL^{*} \); (2) \( \sigma^{*} \) traces (using the implicit tracing algorithm above) to some user outside of the coalition \( U \setminus RL^{*} \), or the tracing algorithm fails; and (3) \( \sigma^{*} \) is nontrivial, i.e., \( A \) did not obtain \( \sigma^{*} \) by making a signing query at \( M^{*} \).

We denote by \( \text{Succ}_{PT,A} \) the probability that \( A \) wins the game. The probability is taken over the coin tosses of \( A \) and the randomized key generation and signing algorithms.

The security proof for our system is set in the random oracle model [5] and therefore we include in our security definitions an extra parameter \( q_{t} \) denoting the number of random oracle calls that the adversary issues.

**Definition 1.** An aggregate forger \( A (t, q_{t}, q_{s}, n, \epsilon) \)-breaks traceability in an \( n \)-user VLR group signature scheme if \( A \) runs in time at most \( t \); \( A \) makes at most \( q_{t} \) hash oracle queries and at most \( q_{s} \) signing queries; and \( \text{Succ}_{PT,A} \) is at least \( \epsilon \).

**Selfless-anonymity.** In the selfless-anonymity game, the adversary’s goal is to determine which of two keys generated a signature. He is not given access to either key. The game is defined as follows.

**Setup.** The challenger runs the KeyGen algorithm, obtaining group parameters \( gpk, gsk \), and \( grt \). It provides the adversary \( A \) with \( gpk \).

**Queries.** Algorithm \( A \) can make queries of the challenger, as follows.

**Signing.** Algorithm \( A \) requests a signature on an arbitrary message \( M \) for the user at index \( i \), where \( 1 \leq i \leq n \). The challenger computes \( \sigma \leftarrow \text{Sign}(gpk, gsk[i], M) \) and returns the signature \( \sigma \) to \( A \).

**Corruption.** Algorithm \( A \) requests the private key of the user at index \( i \), \( 1 \leq i \leq n \). The challenger responds with \( gsk[i] \).

**Revocation.** Algorithm \( A \) can request the revocation token of the user at index \( i \), \( 1 \leq i \leq n \). The challenger responds with \( grt[i] \).

**Challenge.** Algorithm \( A \) outputs a message \( M \) and two indices \( i_{0} \) and \( i_{1} \). It must have made neither a corruption nor a revocation query at either index. The challenger chooses a bit \( b \xleftarrow{} \{0,1\} \) uniformly at random, computes a signature on \( M \) by user \( i_{b} \) as \( \sigma^{*} \leftarrow \text{Sign}(gpk, gsk[i_{b}], M) \), and provides \( \sigma^{*} \) to \( A \).

**Restricted Queries.** After obtaining the challenge, algorithm \( A \) can make additional queries of the challenger, restricted as follows.

**Signing.** Algorithm \( A \) can make signing queries as before.

**Corruption.** As before, but \( A \) cannot make corruption queries at \( i_{0} \) and \( i_{1} \).

**Revocation.** As before, but \( A \) cannot make revocation queries at \( i_{0} \) and \( i_{1} \).

**Output.** Finally, \( A \) outputs a bit \( b' \), its guess of \( b \). The adversary wins if \( b' = b \).

We define \( A \)'s advantage in winning the game as \( \text{Succ}_{PT,A} \) as \( |\Pr[b = b'] - 1/2| \). The probability is taken over the coin tosses of \( A \), of the randomized key generation and signing algorithms, and the choice of \( b \). Note that \( A \) can make no more than \( n - 2 \) corruption and revocation queries.

**Definition 2.** An aggregate adversary \( A (t, q_{t}, q_{s}, n, \epsilon) \)-breaks selfless-anonymity in an \( n \)-user VLR group signature scheme if: \( A \) runs in time at most \( t \); \( A \) makes at most \( q_{t} \) hash oracle queries and at most \( q_{s} \) signing queries; and \( \text{Adv}_{PA,A} \) is at least \( \epsilon \).

**Definition 3.** A group signature scheme with verifier-local revocation is \( (t, q_{t}, q_{s}, n, \epsilon) \)-secure in the VLR security model if: it is correct; no algorithm \( (t, q_{t}, q_{s}, n, \epsilon) \)-breaks its traceability; and no algorithm \( (t, q_{t}, q_{s}, n, \epsilon) \)-breaks its selfless-anonymity.

We note that a signature scheme that satisfies the VLR security model above is existentially unforgeable under a chosen message attack. This follows immediately from the traceability game.

### 3. BACKGROUND

Our VLR group signature scheme makes use of bilinear groups. The security of the scheme depends on the Strong Diffie-Hellman assumption and the Decision Linear assumption. In this section, we review the definitions of bilinear groups and of the complexity assumptions.

#### 3.1 Bilinear Groups

We first review a few concepts related to bilinear maps. Although many groups with a useful bilinear map are based on elliptic curves, our definitions are abstract and do not require any familiarity with elliptic curves. We follow the notation of Boneh, Lynn, and Shacham [8]:

1. \( G_{1} \) and \( G_{2} \) are two (multiplicative) cyclic groups of prime order \( p \).
2. \( g_{1} \) is a generator of \( G_{1} \) and \( g_{2} \) is a generator of \( G_{2} \);
3. \( \psi \) is an efficiently computable isomorphism from \( G_{2} \) to \( G_{1} \), with \( \psi(g_{2}) = g_{1} \); and
4. \( e \) is an efficiently computable bilinear map \( e : G_{1} \times G_{2} \rightarrow G_{T} \) with the following properties:
   - **Bilinear:** for all \( u \in G_{1}, v \in G_{2} \) and \( a, b \in \mathbb{Z} \), \( e(a^{u}, v^{b}) = e(u,v)^{ab} \).
   - **Non-degenerate:** \( e(g_{1}, g_{2}) \neq 1 \).

Throughout the paper, we consider bilinear maps \( e : G_{1} \times G_{2} \rightarrow G_{T} \) where all groups \( G_{1}, G_{2}, G_{T} \) are multiplicative and of prime order \( p \). One could set \( G_{1} = G_{2} \). However, we allow for the more general case where \( G_{1} \neq G_{2} \) so that...
our constructions can make use of certain families of non-supersingular elliptic curves defined by Miyaji et al. [16]. In this paper we only use the fact that \( G_1 \) can be of size approximately \( 2^{103} \), elements in \( G_1 \) are 171-bit strings, and discrete log in \( G_1 \) is as hard as discrete log in \( \mathbb{Z}_p^* \) where \( p \) is a 1020-bit prime power. We will use these groups to construct short VLR group signatures.

We say that two groups \( (G_1, G_2) \) as above are a bilinear group pair if the group action \( G_1 \) and \( G_2 \), the map \( \psi \), and the bilinear map \( \epsilon \) are all efficiently computable.

To keep the discussion general, we simply assume that \( G \) is a subgroup of the group of points of an elliptic curve \( \mathbb{E} \) over a finite field \( \mathbb{F}_p \), the trace map on the curve can be used as this isomorphism.

In this case, \( G_1 \subseteq E(\mathbb{F}_p) \) and \( G_2 \subseteq E(\mathbb{F}_p^*). \)

### 3.2 Complexity Assumptions

The security of our VLR group signatures relies on the difficulty of two problems: the Strong Diffie-Hellman problem and the Decision Linear problem. We describe each of these problems in turn.

#### 3.2.1 The Strong Diffie-Hellman Assumption

Let \( G_1, G_2 \) be cyclic group of prime order \( p \), where possibly \( G_1 = G_2 \). Let \( g_1 \) be a generator of \( G_1 \) and \( g_2 \) a generator of \( G_2 \).

**q-Strong Diffie-Hellman Problem.** The \( q \)-SDH problem in \( (G_1, G_2) \) is defined as follows: given a \((q + 2)\)-tuple \((g_1, g_2, g_1^{\gamma_1}, \ldots, g_1^{\gamma_q})\) as input, output a pair \((g_2^{\gamma_1}, x)\), where \( x \in \mathbb{Z}_p^* \). An algorithm \( A \) has advantage \( \epsilon \) in solving \( q \)-SDH in \( (G_1, G_2) \) if

\[
\Pr \left[ A(g_1, g_2, g_1^{\gamma_1}, \ldots, g_1^{\gamma_q}) = (g_2^{\gamma_1}, x) \right] \geq \epsilon ,
\]

where the probability is over the random choice of generator \( g_2 \) in \( G_2 \) (with \( g_1 \leftarrow \psi(g_2) \)), of \( \gamma \) in \( \mathbb{Z}_p^* \), and of the random bits of \( A \).

**Definition 4.** We say that the \((q, t, \epsilon)\)-SDH assumption holds in \((G_1, G_2)\) if no \( t \)-time algorithm has advantage at least \( \epsilon \) in solving the \( q \)-SDH problem in \((G_1, G_2)\).

Occasionally we drop the \( t \) and \( \epsilon \) and refer to the \((q, \epsilon)\)-SDH assumption rather than the \((q, t, \epsilon)\)-SDH assumption. The \( q \)-SDH assumption was recently used by Boneh and Boyen [6] to construct a short signature scheme with random oracles. To gain confidence in the assumption they prove that it holds in generic groups [19]. The assumption has properties similar to the Strong-RSA assumption [3] and we exploit these properties to build short VLR group signatures. Mitsumari et al. [15] use a related assumption (where \( x \) is part of the input given to the adversary) in a tracing traitors system.

#### 3.2.2 The Decision Linear Assumption

With \( g_1 \in G_1 \) as above, along with arbitrary generators \( u, v, h \), and \( h \) of \( G_1 \), consider the following problem:

**Decision Linear on \( G_1 \):** Given \( u, v, h, u^a, v^b, h^c \in G_1 \) as input, output yes if \( a + b = c \) and no otherwise.

One can easily show that an algorithm for solving Decision Linear in \( G_1 \) gives an algorithm for solving DDH in \( G_1 \). The converse is believed to be false. That is, it is believed that Decision Linear is a hard problem even in bilinear groups where DDH is easy. More precisely, we define the advantage of an algorithm \( A \) in deciding the Decision Linear problem on \( G_1 \) as

\[
\text{Adv Linear}_A \text{ def } = \left| \Pr \left[ A(u, v, h, u^a, v^b, h^{a+b}) = \text{yes} \right] - \Pr \left[ A(u, v, h, u^a, v^b, h^c) = \text{yes} \right] \right| .
\]

The probability is over the uniform random choice of the parameters to \( A \), and over the coin tosses of \( A \). We say that an algorithm \( A \) \((t, \epsilon)\)-decides Decision Linear on \( G_1 \) if \( A \) runs in time at most \( t \), and \( \text{Adv Linear}_A \) is at least \( \epsilon \).

**Definition 5.** We say that the \((t, \epsilon)\)-Decision Linear assumption holds in \( G_1 \) if no \( t \)-time algorithm has advantage at least \( \epsilon \) in solving the Decision Linear problem in \( G_1 \).

The Decision Linear assumption was recently introduced by Boneh, Boyen, and Shacham [7]. They prove that the problem is intractable in generic bilinear groups.

### 4. SHORT VLR GROUP SIGNATURES

In this section, we describe in detail our VLR group signature based on SDH. In the next section, we give intuition for how the scheme is derived.

Consider bilinear groups \( (G_1, G_2) \) with isomorphism \( \psi \) and respective generators \( g_1 \) and \( g_2 \), as in Section 3.1. The scheme employs hash functions \( H_0 \) and \( H_i \), with respective ranges \( G_2 \) and \( \mathbb{Z}_p \), treated as random oracles.

**KeyGen\((n)\).** The key generation algorithm takes as input \( n \), the number of user keys to generate. It proceeds as follows:

1. Select a generator \( g_2 \) in \( G_2 \) uniformly at random, and set \( g_1 \leftarrow \psi(g_2) \).
2. Select \( \gamma \leftarrow \mathbb{Z}_p^* \) and set \( w = g_2^\gamma \).
3. Using \( \gamma \), generate for each user an SDH tuple \((A_i, x_i)\) by selecting \( x_i \leftarrow \mathbb{Z}_p^* \) such that \( \gamma + x_i \neq 0 \), and setting \( A_i = g_1^{\gamma + x_i} \).

The group public key is \( \text{gpk} = (g_1, g_2, w) \). Each user’s private key is her tuple \( \text{gsk}[i] = (A_i, x_i) \). The re-vocation token corresponding to a user’s key \((A_i, x_i)\) is \( \text{grt}[i] = x_i \). The algorithm outputs \((\text{gpk}, \text{gsk}, \text{grt})\). No party is allowed to possess \( \gamma \); it is only known to the private-key issuer.

**Sign\((\text{gpk}, \text{gsk}[i], M)\).** The signing algorithm takes as input a group public key \( \text{gpk} = (g_1, g_2, w) \), a user private key \( \text{gsk}[i] = (A_i, x_i) \), and a message \( M \in \{0, 1\}^* \), and proceeds as follows.

1. Pick a random nonce \( r \leftarrow \mathbb{Z}_p \). Obtain generators \((\hat{u}, \hat{v}) \in G_2 \) from \( H_0 \) as

\[
(\hat{u}, \hat{v}) \leftarrow H_0(\text{gpk}, M, r) \in G_2^2 ,
\]

and compute their images in \( G_1 \):

\[
u \leftarrow \psi(\hat{u}) , \quad v \leftarrow \psi(\hat{v}) .
\]
Verify using the curves described in [8] one can take approximately the same as a standard 1024-bit RSA signature, 171 bits. Thus, the total group signature length is 1192 bits.

G comprises two elements of Signature Length.

1. **Signature Check.** Check that \( \sigma \) is a valid signature, as follows.

1. Compute \( \bar{u} \) and \( \bar{v} \) using equation (2), and their images \( u \) and \( v \) in \( G_1 \):

   \[
   u \leftarrow \psi (\bar{u}) \quad \text{and} \quad v \leftarrow \psi (\bar{v}) .
   \]

2. Rederive \( R_1 \), \( R_2 \), and \( R_3 \) as:

   \[
   \bar{R}_1 \leftarrow u^{-\bar{s}x}/T_1^x, \quad \bar{R}_3 \leftarrow T_1^x u^{-s_3}
   \]

   \[
   R_2 \leftarrow e(T_2, g_2)^{\bar{s}x} e(v, w)^{-\alpha s_3} e(v, g_2)^{-s_3} \cdot (e(T_2, w)/e(g_1, g_2))^\epsilon .
   \]

3. Check that the challenge \( c \) is correct:

   \[
   c \leftarrow H(gpk, M, r, T_1, T_2, \bar{R}_1, \bar{R}_2, \bar{R}_3) .
   \]

   If it is, accept. Otherwise, reject.

2. **Revocation Check.** For each element \( A \in RL \), check whether \( \bar{A} \) is encoded in \((T_1, T_2)\) by checking if:

   \[
   e(T_2/A, \bar{u}) \leftarrow e(T_1, \bar{v}) .
   \]

   If no element of \( RL \) is encoded in \((T_1, T_2)\), the signer of \( \sigma \) has not been revoked.

   The algorithm outputs valid if both phases accept, invalid otherwise.

### Performance

Signature generation requires two applications of the isomorphism \( \psi \). Computing the isomorphism takes roughly the same time as an exponentiation in \( G_1 \) (using fast computations of the trace map). Thus, signature generation requires about 8 exponentiations (or multi-exponentiations) and 2 bilinear map computations. Signature verification takes 6 exponentiations and \( 3 \times 2 \) RL computations of the bilinear map. A far more efficient revocation check algorithm, whose running time is independent of \(|RL|\), is described in Section 7.

We now prove the correctness of the VLR group signature scheme. The proofs of the selflessness-anonymity and traceability of the scheme are given in Section 6.

**Theorem 1.** The VLR group signature scheme is correct, as defined in equation (1).

**Proof.** Consider public parameters \( gpk = (g_1, g_2, w) \); secret-key vector \( gsk \) where, for each \( \iota \), \( gsk[\iota] = (A_i, x_i) \), an SDH tuple, i.e., a tuple satisfying \( e(A_i, w g_2^\iota) = e(g_1, g_2) \); and revocation-token list \( grt \) where \( grt[\iota] = \hat{A}_i \), as output by the key generation algorithm.

An honest signer with private key \((A_1, x_1)\) generates a signature \( \sigma = (r, T_1, T_2, c, s_1, s_2, s_3) \) by following the signing algorithm described above. In particular, the signer computes the generators \( \bar{u} \) and \( \bar{v} \) according to equation (2), so the verifier uses the same generators. Now, the first phase of the signature verification algorithm accepts a signature if the output of \( H \) equals the challenge \( c \). This will only be true (except with negligible probability) when all inputs to \( H \) are exactly the same for the verifier as for the signer. An honest signer’s signature includes all these inputs except \( R_1 \), \( R_2 \), and \( R_3 \), which are rederived by the verifier. We must therefore show that the values rederived by the verifier using equations (6) equal those derived by the signer using equations (4). First,

\[
\bar{R}_1 = u^{-\bar{s}x}/T_1 = u^{-\alpha s\bar{x}}/(u^\alpha)^\epsilon = u^\alpha = R_1 ,
\]

so \( \bar{R}_1 = R_1 \). Further,

\[
\bar{R}_3 = T_1^x u^{-s_3} = (u^{\alpha s\bar{x}}/e(v, w)^{-\alpha s_3} \cdot u^{-r_2-e\alpha s_3}) = e(u^\alpha)^s \cdot u^{-r_2} = T_1^x u^{-r_2} = R_3 ,
\]

so \( \bar{R}_3 = R_3 \). Finally,

\[
R_2 = e(T_2, g_2)^{\bar{s}x} \cdot e(v, w)^{-\alpha s_3} \cdot e(v, g_2)^{-s_3} \cdot (e(T_2, w)/e(g_1, g_2))^\epsilon
\]

\[
\frac{e(T_2, g_2)^{\bar{s}x} \cdot e(v, w)^{-\alpha s_3} \cdot e(v, g_2)^{-s_3}}{e(g_1, g_2)^\epsilon}
\]

\[
= R_2 \cdot \left( \frac{e(A_1, w g_2^\iota)}{e(g_1, g_2)} \right)^\epsilon = R_2 ,
\]

so \( R_2 = R_2 \). The last equality follows from the SDH equation. Thus (7) will be satisfied.

In a signature generated by the signing algorithm, we have \( T_1 = \psi (\bar{u})^\alpha \) and \( T_2 = A_i \psi (\bar{v})^\alpha \) for some \( \alpha \). The revocation check algorithm will reject a signature as originating from a revoked user with token \( A \) exactly when \( (u, \bar{v}, T_1, T_2/A) \) is a co-Diffie-Hellman tuple, i.e., when \( A \) equals \( \hat{A}_i \). Thus the group signature verification algorithm will accept a signature as valid exactly when \( A_i \) is not included in its input \( RL \), as required. □

### Signature Length

A group signature in the system above comprises two elements of \( G_1 \) and five elements of \( Z_{\ell p} \). When using the curves described in [8] one can take \( p \) to be a 170-bit prime and use a group \( G_1 \) where each element is 171 bits. Thus, the total group signature length is 1192 bits or 149 bytes. With these parameters, security is approximately the same as a standard 1024-bit RSA signature, which is 128 bytes.
5. INTUITION

The VLR group signature scheme presented in Section 4 above is derived, via a variant of the Fiat-Shamir heuristic [13], from a new protocol for proving possession of an SDH tuple. We present this protocol below to give intuition into the construction of our VLR group signature scheme.

The protocol is a proof of knowledge, which means that by rewinding a prover it is possible to extract an SDH pair. The protocol is intentionally not zero-knowledge; a verifier in possession of a revocation token can determine whether he is interacting with a revoked prover.

The public values are $g_1 \in G_1$ and $g_2, w \in G_2$. Here $g_2$ is a random generator of $G_2$, $g_1$ equals $\psi(g_2)$, and $w$ equals $g_2^\gamma$ for some (secret) $\gamma \in \mathbb{Z}_p$. The prover wishes to demonstrate possession of a pair $(A, x)$, where $A \in G_1$ and $x \in \mathbb{Z}_p$, such that $A^{x+\gamma} = g_1$. Such a pair satisfies $\alpha(A, w g_2^\gamma) = \epsilon(g_1, g_2)$. We use a generalization of Schnorr’s protocol for proving knowledge of discrete logarithm [18] in a group of prime order.

Protocol 1. Bob, the verifier, selects elements $\hat{u}$ and $\hat{v}$ uniformly at random from $G_2$ and sends them to Alice, the prover. Alice sets $u = \psi(\hat{u})$ and $v = \psi(\hat{v})$. She selects exponent $\alpha \in \mathbb{Z}_p$, and computes

\[ T_1 = u^\alpha \quad \text{and} \quad T_2 = Av^\alpha.\]

Alice and Bob then undertake a proof of knowledge of values $(\alpha, x, \delta)$ satisfying the following three relations:

\[ u^\alpha = T_1, \quad T_1^x = u^\delta, \quad e(T_2 v^{-\alpha}, w g_2^\delta) = e(g_1, g_2).\]

This proof of knowledge proceeds as follows. Alice computes a helper value $\delta = \alpha x$. She then picks binding values $r_{\alpha}, r_x, r_\delta$ at random from $\mathbb{Z}_p$. She computes three values based on all these:

\[ R_1 = u^{-\alpha}, \quad R_2 = T_1^x \cdot u^{-r_\delta}, \quad R_3 = T_2 \cdot e(T_2, g_2)^{r_x} \cdot e(v, w)^{r_\delta} \cdot e(v, g_2)^{-r_\delta}.\]

She then sends $(T_1, T_2, R_1, R_2, R_3)$ to Bob. Bob sends a challenge value $c$ chosen uniformly at random from $\mathbb{Z}_p$. Alice computes and sends back $s_{\alpha} = r_{\alpha} + c x$, $s_x = r_x + c x$, and $s_\delta = r_\delta + c \delta$. Finally, Bob verifies the following three equations:

\[ u^{s_{\alpha}} = T_1^c \cdot R_1, \quad e(T_2, g_2)^{s_x} \cdot e(v, w)^{-s_\delta} \cdot e(v, g_2)^{-s_\delta} = (e(g_1, g_2)/e(T_2, w))^c \cdot R_2, \quad T_1^{s_x} u^{-s_\delta} \overline{=} R_3.\]

Bob accepts if all three hold. Applying a standard variant of the Fiat-Shamir heuristic to this protocol produces the signature scheme of the previous section.

The protocol above is (by design) not a zero-knowledge protocol. Given $(T_1, T_2)$ and a candidate $A$, anyone can check whether $A$ is ElGamal-encrypted in $(T_1, T_2)$ by checking whether $e(T_2/A, \hat{u}) \equiv e(T_1, \hat{v})$. Below, however, we show that the protocol has an extractor and, given a $(T_1, T_2)$ pair, can be simulated. The correctness of the protocol follows from Theorem 1.

**Lemma 1.** For any $(\hat{u}, \hat{v}, T_1, T_2)$, Transcripts of Protocol 1 can be simulated.

**Proof.** Choose challenge $c \in \mathbb{Z}_p$. Select $s_{\alpha}, s_x, s_\delta \in \mathbb{Z}_p$, and set $R_1 = u^c / T_1^c$. Then equation (8) is satisfied. With $\alpha$ and $c$ fixed, a choice for either of $r_{\alpha}$ or $s_{\alpha}$ determines the other, and a uniform random choice of one gives a uniform random choice of the other. Therefore $s_{\alpha}$ and $R_1$ are distributed as in a real transcript.

Select $s_x, s_\delta \in \mathbb{Z}_p$. Now, $A$ and $\alpha$ are fixed by $T_1$ and $T_2$, $x$ is implicitly fixed by the SDH equation for $A$, $r_x$ is fixed by $x$ and $s_x$, and $\delta$ is fixed as $x \alpha$. Select $s_\alpha \in \mathbb{Z}_p$; a uniform distribution on this gives a uniform distribution on $r_\delta$. Set $R_3 = T_1^{c_x} u^{-s_\delta}$. Again, all the computed values are distributed as in a real transcript. Finally, set

\[ R_2 = e(T_2, g_2)^{\alpha x} \cdot e(v, w)^{-s_\delta} \cdot e(v, g_2)^{-s_\delta} \cdot (e(T_2, w)^c).\]

This $R_2$ satisfies (9), so it, too, is properly distributed.

Finally, the simulator outputs the transcripts $(\hat{u}, \hat{v}, T_1, T_2, R_1, R_2, R_3, c, s_{\alpha}, s_x, s_\delta)$. As argued above, this transcript is distributed identically to transcripts of Protocol 1 for the given $(\hat{u}, \hat{v}, T_1, T_2)$.

**Lemma 2.** There exists an extractor for Protocol 1 that extracts an SDH pair from a convincing prover.

**Proof.** Suppose that an extractor can rewind a prover in the protocol above. The verifier sends $\hat{u}, \hat{v}$ to the prover. Let $u = \psi(\hat{u})$ and $v = \psi(\hat{v})$. The prover then sends $T_1, T_2$ and $R_1, R_2, R_3$. To challenge value $c$, the prover responds with $s_{\alpha}, s_x, s_\delta$. To challenge value $c' \neq c$, the prover responds with $s'_{\alpha}, s'_x, s'_\delta$. If the prover is convincing, all three verification equations hold for each set of values.

For brevity, let $\Delta c = c - c'$, $\Delta s_{\alpha} = s_{\alpha} - s'_{\alpha}$, and similarly for $\Delta s_x$ and $\Delta s_\delta$.

Consider (8) above. Dividing the two instances of this equation, we obtain $u^{s_{\alpha}} = T_1^{c_x}$. The exponents are in a group of known prime order, so we can take roots; let $\hat{\alpha} = \Delta s_{\alpha}/\Delta c$. Then $u^{\hat{\alpha}} = T_1$.

Now consider (10) above. Dividing the two instances gives $T_1^{s_x} = u^{\Delta s_x}$. Substituting $T_1 = u^{\hat{\alpha}}$ gives $u^{\hat{\alpha} s_x - s_\delta}$, or $\Delta s_x = \hat{\alpha} \Delta s_\delta$.

Finally, dividing the two instances of (9), we obtain

\[ (e(g_1, g_2)/e(T_2, w))^{\Delta c} = e(T_2, g_2)^{\Delta s_x} \cdot e(v, w)^{-\Delta s_\delta} \cdot e(v, g_2)^{-\Delta s_\delta}.\]

Taking $\Delta c$-th roots, and letting $\hat{x} = \Delta s_x/\Delta c$, we obtain

\[ e(g_1, g_2)/e(T_2, w) = e(T_2, g_2)^{\hat{x}} \cdot e(v, w)^{-\hat{x}} \cdot e(v, g_2)^{-\hat{x}}.\]

This can be rearranged as

\[ e(g_1, g_2) = e(T_2 v^{-\hat{x}}, w g_2^\hat{x}), \]

or, letting $\hat{A} = T_2 v^{-\hat{x}}, \hat{w} g_2^\hat{x}$

\[ e(\hat{A}, \hat{w} g_2^\hat{x}) = e(g_1, g_2).\]

Thus the extractor obtains an SDH tuple $(\hat{A}, \hat{x})$. Moreover, the $\hat{A}$ in this SDH tuple is, perforce, the same as that in the ElGamal encryption $(T_1, T_2)$. In other words, the extractor recovers the same $A$ that a revocation-checker matches.

6. PROOF OF SECURITY

We show that the scheme described in Section 4 is a VLR group signature scheme. The correctness of the scheme was
demonstrated in Theorem 1, above. Below we prove the self-
lessness-anonymity and traceability of the scheme, as defined in
Section 2.

6.1 Selfless-Anonymity

Lemma 3. The VLR group signature scheme in \((G_1, G_2)\)
has \((t, q_u, q_g, n, \epsilon)\) selfless anonymity in the random oracle
model assuming the \((t, \epsilon)\) Decision Linear assumption holds
in the group \(G_2\) for \(\epsilon = \frac{1}{2} \left( \frac{1}{2^t} - \frac{2q_u n}{p} \right) \approx \epsilon/2n^2\).

Proof. Suppose algorithm \(\mathcal{A}\) \((t, q_u, q_g, n, \epsilon)\)-breaks
the selflessness of the VLR group signature scheme. We
build an algorithm \(\mathcal{B}\) that breaks the Decision Linear as-
sumption in \(G_2\). Algorithm \(\mathcal{B}\) is given as input a 6-tuple
\((u_0, u_1, \psi, h_0, h_1, Z) \in G_2^6\) where \(u_0, u_1, \psi, h_0, h_1, Z \in G_2\).
Algorithm \(\mathcal{B}\) next picks random \(r, c, a, b \in \mathbb{Z}_p\) and
computes the corresponding \(R_1, R_2, R_3\) using equations (6). In the unlikely
event that \(\mathcal{A}\) has already issued a hash query ei-
ther for \(H(gpk, M, r, \psi(T_1), \psi(T_2), R_1, R_2, R_3)\) or
for \(H_0(gpk, M, r)\), \(\mathcal{B}\) reports failure and termi-
nates. Since \(r\) is random in \(\mathbb{Z}_p\) this happens with
probability at most \(q_u / p\). Otherwise, \(\mathcal{B}\) defines
\(H(gpk, M, r, \psi(T_1), \psi(T_2), R_1, R_2, R_3) = c\)
\(H_0(gpk, M, r) = (\hat{u}, \hat{v}).\)

Challenge Algorithm \(\mathcal{B}\) then computes the signature \(\sigma\)
\(\sigma = (r, \psi(T_1), \psi(T_2), c, s_3, s_5, s_7)\), and gives \(\sigma\) to \(\mathcal{A}\).
Note that by Lemma 1, \(\sigma\) is a properly dis-
tributed signature under user \(i\)'s private key.
• Corruption queries and revocation queries: if \(\mathcal{A}\)
ever issues a corruption of revocation query for
users \(i_0\) or \(i_1\) then \(\mathcal{B}\) reports failure and aborts.

Phase 2. Algorithm \(\mathcal{A}\) issues restricted queries. \(\mathcal{B}\) responds
as in Phase 1.

Output. Eventually, \(\mathcal{A}\) outputs its guess \(b' \in \{0, 1\}\) for
\(b\). If \(b = b'\) then \(\mathcal{B}\) outputs 0 (indicating that \(Z\)
is random in \(G_2\)); otherwise \(\mathcal{B}\) outputs 1 (indicating that
\(Z = v^{a+b}\)).
not cause \(B\) to abort is at least \(1/n^2\). It now follows that \(B\) solves the given linear challenge with advantage at least 
\[
\frac{1}{\epsilon^2} \left( \frac{3}{2} - \frac{2n\epsilon}{p} \right),
\]
as required. \(\square\)

### 6.2 Traceability

**Theorem 2.** If \(SDH\) is \((q, t', \epsilon')\)-hard on \((G_1, G_2)\), then the VLR group signature scheme is \((t, q_B, q_A, n, \epsilon)\)-traceable, where \(n = q - 1\), \(\epsilon = 4n\sqrt{2}q_Bn + n/p\), and \(t = \Theta(1) \cdot t'\).

Proof. Our proof proceeds in three parts. First, we describe a framework for interacting with an algorithm that wins a traceability game. Second, we show how to instantiate this framework appropriately for different types of such breaker algorithms. Third, we show how to apply the forking lemma [17] to the framework instances, obtaining SDH solutions.

**Interaction Framework.** Suppose we have given an algorithm \(A\) that breaks the traceability of the VLR group signature scheme. We describe a framework for interacting with \(A\).

**Setup.** We are given groups \((G_1, G_2)\) as above, with respective generators \(g_1\) and \(g_2\). We are also given \(w = g_2^x \in G_2\), and a list of pairs \((A_i, x_i)\) for \(i = 1, \ldots, n\). For each \(i\), either \(x_i = \ast\), indicating that the \(x_i\) corresponding to \(A_i\) is not known, or else \((A_i, x_i)\) is an SDH pair, and \(\epsilon(A, w g_2^{x_i}) = \epsilon(g_1, g_2)\). We then run \(A\), giving it the group public key \((g_1, g_2, w)\) and the users’ revocation tokens \(\{A_i\}\). We answer its oracle queries as follows.

**Hash Queries.** At any time, \(A\) can query the hash functions to obtain generators \((\hat{u}, \hat{v})\) or challenge \(c\). We respond with random values while maintaining consistency, made again.

**Signature Queries.** Algorithm \(A\) asks for a signature on message \(M\) by a key at index \(i\). If \(s_i \neq \ast\), we follow the group signing procedure with key \((A_i, x_i)\) to obtain a signature \(\sigma\) on \(M\), and return \(\sigma\) to \(A\).

Otherwise \(s_i = \ast\). We pick a nonce \(r \overset{\$}{\leftarrow} Z_p\), obtain generators \((\hat{u}, \hat{v}) = H_0(gpk, M, r)\), and set \(u = \psi(\hat{u})\) and \(v = \psi(\hat{v})\). We then pick \(\alpha \overset{\$}{\leftarrow} Z_p\), set \(T_1 = u^\alpha\), and \(T_2 = A g_1^\alpha\) and run the Protocol 1 simulator with values \((\hat{u}, \hat{v}, T_1, T_2)\). The simulator returns a transcript \((\hat{u}, \hat{v}, T_1, T_2, R_1, R_2, R_3, c, s_a, s_x, s_s)\) from which we derive a VLR group signature \(\sigma = (r, T_1, T_2, c, s_a, s_x, s_s)\). In addition, we must patch the hash oracle at \((M, r, T_1, T_2, R_1, R_2, R_3)\) to equal \(c\). If this causes a collision, i.e., if we previously set the oracle at this point to some other \(c'\), we declare failure and exit. Otherwise, we return \(\sigma\) to \(A\). A signature query can trigger a hash query, which we charge against \(A\)’s hash query limit to simplify the accounting.

**Private Key Queries.** Algorithm \(A\) asks for the private key of the user at some index \(i\). If \(x_i \neq \ast\), we return \((A_i, x_i)\) to \(A\). Otherwise, we declare failure and exit.

**Output.** Finally, if algorithm \(A\) is successful, it outputs a forged VLR group signature \(\sigma = (r, T_1, T_2, c, s_a, s_x, s_s)\) on a message \(M\) with nonce \(r\), along with a revocation list \(RL^t\). We apply the implicit revocation algorithm, with revocation tokens \(\{A_i\}\) to determine which \(A^t\) is encoded in \((T_1, T_2)\). This \(A^t\) cannot be on \(RL^t\); if it were, the signature would have been rejected as invalid. Thus for the forger to be nontrivial, \(A^t\) must also be outside the adversary’s coalition \(U\). If \(A^t\) does not equal \(A_i\) for any \(i\), we output \(\ast\). Otherwise, \(A^t = A_i^t\) for some \(i^t\). If \(s_i^t = \ast\), we output \(\ast\). If, however, \(s_i^t \neq \ast\), we declare failure and exit.

As implied by the output phase of the framework above, there are two types of forger algorithm. Type I forgers output a forgery \(\sigma\) on a message \(M\) that encodes some identity \(A^t \not= \{A_1, \ldots, A_n\}\). Type II forgers output a forgery that encodes an identity \(A^t\) such that \(A^t = A_i^t\) for some \(i^t\), and the forger did not make a private-key oracle query at \(i^t\). We treat these two types of forger differently.

Given a \(q\)-SDH instance \((g_1, g_2, (g_2^i)^{-y} \cdot (g_2^j)^{-y} \cdot \ldots \cdot (g_2^k)^{-y})\), we apply the technique of Boneh and Boyen’s Lemma 3.2 [6], obtaining generators \(g_1 \in G_1, g_2 \in G_2, w = g_2\), along with \(q - 1\) SDH pairs \((A_i, x_i)\) such that \(\epsilon(A, w g_2^{x_i}) = \epsilon(g_1, g_2)\) for each \(i\). Any SDH pair \((A, x)\) besides these \(q - 1\) pairs can be transformed into a solution to the original \(q\)-SDH instance, again using Boneh and Boyen’s Lemma 3.2.

**Type I Forger.** Against a \((t, q_B, q_A, n, \epsilon)\)-Type I forger \(A\), we turn an instance of \((n + 1)\)-SDH into values \((g_1, g_2, w)\), and \(n\) SDH pairs \((A_i, x_i)\). We then apply the framework to \(A\) with these values. Algorithm \(A\)’s environment is perfectly simulated, and the framework succeeds whenever \(A\) succeeds, so we obtain a Type I forgery with probability \(\epsilon\).

**Type II Forger.** Against a \((t, q_B, q_A, n, \epsilon)\)-Type II forger \(A\), we turn an instance of \(n\)-SDH into values \((g_1, g_2, w)\), and \(n - 1\) SDH pairs. These pairs we distribute amongst \(n\) pairs \((A_i, x_i)\). The unfilled entry at random index \(i^t\) we fill as follows. Pick \(A^t \overset{\$}{\leftarrow} G_1\), and set \(x^t = \ast\), a placeholder value. Now we run \(A\) under the framework. The framework declares success only if \(A\) never queries the private key oracle at \(i^t\), but forges a group signature that traces to \(A_i^t\). It is easy to see that the framework simulation is perfect unless \(A\) queries the private key oracle at \(i^t\). Because the protocol simulator invoked by the signing oracle produces group signatures that are indistinguishable from those of a user whose SDH tuple includes \(A_i^t\), the value of \(i^t\) is independent of \(A\)’s view unless and until it queries the private key oracle at \(i^t\). (Since the hash oracle takes as input five elements of \(G_1\) or \(G_2\) besides the message \(M\), the probability of collision in simulated signing queries is bounded above by \((q_B q_A + q_A^2)/p^9\). Assuming \(q_B \ll q_A < p = |G_1|\), this probability is negligible, and we ignore it in the analysis.) Finally, when \(A\) outputs its forgery \(\sigma\), implicating some user \(i\) whose private key \(A_i^t\) has not requested, the value of \(i^t\) (amongst the users whose keys it has not requested) remains independent of \(A\)’s view. It is easy to see, then, that \(A\) outputs a forged group signature that traces to user \(i^t\) with probability at least \(\epsilon/n\).

**Application of Forger.** Now we show how to use the application of our framework to a Type I or Type II adversary \(A\) to obtain another SDH pair, contradicting the SDH assumption. The remainder of this proof follows closely the methodology and notation of the forking lemma [17].
Let $A$ be a forger (of either type) for which the framework succeeds with probability $\epsilon'$. From here on, we abbreviate signatures as $(M, \sigma_0, c, \sigma_1)$, where $\sigma_0 = (r, u, \hat{v}, T_1, T_2, R_1, R_2, R_3)$, the values given, with $M$, to the random oracle $H$, and from which $c$ is derived, and where $\sigma_1 = (s_a, s_r, s_s)$. (Those values normally omitted from the signature can be recovered as the verification algorithm in Section 4 does.)

We require that $A$ always query $H_0$ at $(M, r)$ before querying $H$ at $(M, r, . . . )$. Any adversary can be modified mechanically into satisfying this condition. This technical requirement means that, even if in rewinding we change the value of $H(M, r, . . . )$, the value of $H_0(M, r)$, and therefore of the $u$ and $v$ used implicitly in the arguments of the $H$ call, remains unchanged.

For any fixed $f_0$ vector of $H_0$ responses, a run of the framework on $A$ is completely described by the randomness string $u$ used by the framework and $A$, by the vector $f_0$ of messages made by the $H_0$ hash oracle, and by the vector $f$ of messages made by the $H$ hash oracle. Let $S$ be the set of tuples $(\omega, f_0, f)$ such that the framework, invoked on $A$, completes successfully with forgery $(M, \sigma_0, c, \sigma_1)$, and $A$ queried the hash oracle $H$ on $(M, \sigma_0)$. In this case, let $\text{Ind}(\omega, f_0, f)$ be the index of $f$ at which $A$ queried $(M, \sigma_0)$. We define $\nu = \text{Pr}[S] = \epsilon'/1/p$, where the $1/p$ term accounts for the possibility that $A$ guessed the hash of $(M, \sigma_0)$ without the hash oracle’s help. For each $j$, let $S_j$ be the set of tuples $(\omega, f_0, f)$ as above and such that $\text{Ind}(\omega, f_0, f) = j$. Let $J$ be the set of auspicious indices $j$ such that $\text{Pr}[\exists \omega, f_0, f \in J \mid S] \geq 1/(2\nu q)$. Then $\text{Pr}[\text{Ind}(\omega, f) \in J \mid S] \geq 1/2$.

Let $f^{[1]}_{j} \equiv f^{[1]}$ be the restriction of $f$ to its elements at indices $a, a + 1, . . . , b$. For each $j \in J$, we consider the heavy-rows lemma [17, Lemma 1] with rows $X = (\omega, f_0, f^{[1]}_{j})$ and columns $Y = (f^{[m]}_{j})$. Clearly $\text{Pr}[(\omega, y) \in S] \geq \nu/(4\nu q)$. Let $J$ be the rows $\Omega_j$ be those rows such that, $\forall (x, y) \in \Omega_j : \text{Pr}[(x, y) \in S_j] \geq \nu/(4\nu q)$. Then, by the heavy-rows lemma, $\text{Pr}[\Omega_j \mid S_j] \geq 1/2$. A simple argument then shows that $\text{Pr}[\exists j \in J : \Omega_j \cap S_j \mid S_j] \geq 1/4$.

Thus, with probability $\nu/4$, the framework, invoked on $A$, succeeds and obtains a forgery $(M, \sigma_0, c, \sigma_1)$ that derives from a heavy row $(x, y) \in \Omega_j$ for some $j \in J$, i.e., an execution $(\omega, f_0, f^{[1]}_{j})$ such that

$$\text{Pr}[\exists j \mid f^{[1]}_{j} = f^{[1]}_{j-1}] \geq \nu/(4\nu q) .$$

If we now rewind the framework and $A$ to the $j$th query and proceed with an oracle vector $f'$ that differs from $f$ from the $j$th entry on, we obtain, with probability at least $\nu/(4\nu q)$, a successful framework completion and a second forgery $(M, \sigma_0, c', \sigma_1')$, with $(M, \sigma_0)$ still queried at $A$’s $j$th hash query. Since the adversary queried $H_0$ at $(M, r)$ (where $r$ is the first element of $\sigma_0$) before he made his $j$th $H$ oracle query, the values of $u$ and $\hat{v}$ in these two forgeries will be the same.

By using the extractor of Lemma 2, we obtain from the forgeries $(\sigma_0, c, \sigma_1)$ and $(\sigma_0, c', \sigma_1')$ an SDH tuple $(A, x)$. The extracted $A$ is the same as the $A$ encoded in $(T_1, T_2)$ in $\sigma_0$. The framework declares success only when the $A$ encoded in $(T_1, T_2)$ is not amongst those whose $x$ it knows. Therefore, the extracted SDH tuple $(A, x)$ is not amongst those that we ourselves can be, and can be transformed, again following the technique of Boneh and Boyen’s Lemma 3.2 [6], to an answer to the posed $q$-SDH problem.

Putting everything together, we have proved the following claims.

**Claim 1.** Using a $(t, q_u, q_o, n, \epsilon)$ Type I forger, we solve an instance of $(n+1)$-SDH with probability $(\epsilon - 1/p)^2/(16\nu q)$ in time $\Theta(1) \cdot t$.

**Claim 2.** Using a $(t, q_u, q_o, n, \epsilon)$ Type II forger, we solve an instance of $n$-SDH with probability $(\epsilon/n - 1/p)^2/(16\nu q)$ in time $\Theta(1) \cdot t$.

We can guess which of the two forger types a particular forger is with probability $1/2$; then assuming the more pessimistic scenario of Claim 2 proves the theorem. □

## 7. EFFICIENT REVOCATION

In our VLR group signature scheme (Section 4), signature verification time grows linearly in the number of revoked users. It is desirable to have a Verifier-Local Revocation system where verification time is constant. In this section we describe a simple modification to the signing and verification algorithms that achieves this at the cost of slightly reduced anonymity.

Consider how our system is used for privacy-preserving attestation: Users connect to various web sites and at each site they perform a private attestation using the group signature issued by the tamper-resistant chip in their machine. For an efficient revocation check, when the chip issues a signature for attesting to a site $S$ it uses the signing algorithm from Section 4 with the small modification that the parameters $u$ and $v$ are generated as:

$$(u, v) \leftarrow H_0(gpk, S, r)$$

where $r$ is random in the range $\{1, . . . , k\}$ and $k$ is a security parameter (e.g., $k = 128$). Note that, unlike Section 4, here $(u, v)$ do not depend on the message being signed. Hence, at a given site $S$ there are only $k$ possible values for the pair $(u, v)$.

Now, suppose site $S$ has been supplied with a revocation list $RL = \{A_1, . . . , A_k\}$. To verify that a signature $\sigma = (r, T_1, T_2, c, s_a, s_r, s_s)$ was not issued by a revoked user the site uses the same procedure as in Section 4:

1. Compute $(u, v) \leftarrow H_0(gpk, S, r)$, and
2. For $i = 1, . . . , b$ check that $e(T_1, v)e(A_i, u) \neq e(T_2, u)$.

Since at site $S$ there are only $k$ possible values for $u$, the value $e(A_i, u)$ can be pre-computed for the entire $RL$ for all possible $u$’s. Thus, site $S$ stores a $|RL| \times k$ table of values, $e(A_i, u)$.

To check revocation, it simply does a table-look up to see if the value $e(T_2, u)/e(T_1, v)$ is in the $r$’th row of the table. If not, then the signature was not issued by a revoked user. Hence, the revocation check takes time independent of the size of $RL$.

The downside is that the scheme is now only partially anonymous. If the user issues two signatures at site $S$ using the same random value $r \in \{1, . . . , k\}$ then the site can test that these two signatures came from the same user. However, signatures issued at different sites are still completely unlinkable. Similarly, signatures issued at the same site using different $r$’s are un-linkable (e.g., with $k = 100$ only 1% of signatures at $S$ are linkable). For some applications, this trade-off between partial differential efficiency and likeliness revocation might be acceptable.
8. CONCLUSIONS AND OPEN PROBLEMS

We have described a short group signature scheme where user revocation only requires sending revocation information to signature verifiers. Our signatures are short: only 149 bytes for a standard security level. They are shorter than group signatures built from the Strong-RSA assumption and are shorter even than BBS short group signatures [7], which do not support verifier-local revocation.

There are still a number of open problems related to VLR signatures. Most importantly, is there an efficient VLR group signature scheme where signature verification time is sub-linear in the number of revoked users, without compromising user privacy?
